

What Positional Embeddings Really Do In Vision Transformers

Anonymous Authors¹

Abstract

Positional embeddings (PEs) in Vision Transformers (ViTs) are typically viewed as mechanisms for injecting absolute spatial information. We show that ViTs trained without PEs can nonetheless recover non-trivial spatial structure using patch content alone, questioning the fundamental functional role of PEs. We demonstrate that PEs induce a sharp increase in early-layer representational diversity, characterized by higher effective rank and reduced token homogenization. However, our analysis reveals that this diversity alone is insufficient for robustness. Using a new metric, Spatial Similarity Distance Correlation (SSDC), we show that PEs facilitate a qualitative shift from content-based to absolute-position-based spatial organization, yielding representations that remain stable under distributional shifts where content-only models fail.

1. Introduction

Vision Transformers (ViTs) have emerged as a powerful alternative to convolutional architectures for visual recognition by modeling images as sequences of patch tokens processed through self-attention mechanisms (Dosovitskiy et al., 2021). Unlike Convolutional Neural Networks (CNNs), ViTs lack strong built-in biases toward locality and translation equivariance. To compensate, most ViT architectures rely on Positional Embeddings (PEs) to inject explicit spatial information, allowing the model to distinguish patches originating from different locations in the image.

Existing studies suggest that ViTs can retain substantial performance even when positional information is removed or degraded (Chu et al., 2023). This potentially indicates that transformers partially reconstruct spatial relationships from patch content alone, analogous to how CNNs learn

implicit positional information from zero-padding (Islam* et al., 2020). These findings challenge the conventional view that PEs are strictly necessary and raise fundamental questions about what functional advantages they provide beyond basic spatial identifiability.

Prior work has largely explored positional embeddings through downstream performance or architectural variations. While informative, such approaches reveal little about how PEs shape the internal representations of the model. In particular, the effects of positional embeddings on the geometry, dimensionality, and stability of token representations across the transformer stack remain poorly understood.

In this work, we adopt a mechanistic perspective to study the role of positional embeddings in ViTs. We analyze the evolution of token representations in the residual stream using tools from representational geometry (Raghu et al., 2021), introducing the Spatial Similarity Distance Correlation (SSDC), a metric designed to quantify how spatial relationships are reflected in token similarity patterns. Using this framework, we systematically compare ViTs trained with and without positional embeddings, examining their impact on representational dimensionality, the spatial reasoning strategies employed by the model, and robustness to distributional shifts such as stylization and noise. Using this framework, we demonstrate that PEs perform three critical functions:

- **Promoting Representational Diversity:** PEs causally increase representational diversity (characterized by high dimensionality and lower token similarities), thereby enriching internal geometric representations.
- **Shifting Spatial Organization Strategy:** We demonstrate that PEs push ViTs from a dominantly content-based strategy of forming internal spatial structure to an absolute-position-based strategy, where the model can always reason "where" a patch is without a great dependence on what it "looks" like.
- **Enhancing Robustness to Distributional Shifts:** We show that this absolute-position-based shift is precisely what allows ViTs with PEs to remain robust to distributional shifts, such as stylization, where local patch content becomes unreliable.

2. Background and Setup

2.1. Vision Transformer Architecture

All models used in our experiments are vanilla Vision Transformers trained from scratch, with approximately 12M parameters. Images are divided into fixed-size patches, which are linearly projected into token embeddings and processed by a stack of self-attention and feedforward layers. When present, positional embeddings are learned parameters optimized jointly with the rest of the model. No architectural modifications or auxiliary inductive biases are introduced beyond standard ViT components.

2.2. Positional Embedding Ablation

To isolate the functional role of positional embeddings, we train a parallel set of models in which positional embeddings are entirely removed. Throughout the paper, we refer to models trained without positional embeddings as *ablated models*, and to models trained with positional embeddings as *intact models*. Apart from the presence or absence of positional embeddings, all architectural choices, optimization settings, and training procedures are held constant.

2.3. Datasets

We evaluate models on CIFAR-10 and a stylized variant derived from CIFAR-10 to assess robustness under distributional shift. The stylized dataset is generated using Adaptive Instance Normalization (AdaIN) with a mixing coefficient $\alpha = 0.1$, which significantly alters texture statistics while preserving coarse spatial structure. Models are trained on standard CIFAR-10 images and evaluated on both the original and stylized datasets.

3. Methods

3.1. Residual Stream Geometry

To analyze the evolution of internal representations across depth, we extract the residual stream at selected layers of the model (layers 0, 2, 4, and 9, where layer 9 corresponds to the final layer). At each layer, we represent the residual stream as a matrix $R \in \mathbb{R}^{T \times C}$, where T denotes the number of tokens and C the embedding dimension. Each row of R corresponds to the residual stream representation of a single token.

Given the singular values $\{\sigma_i\}$ of R , we compute the effec-

tive rank using the participation ratio:

$$\text{ER} = \frac{(\sum_i \sigma_i^2)^2}{\sum_i \sigma_i^4}.$$

Effective rank quantifies the number of dimensions that meaningfully contribute to the representation, with higher values indicating more distributed and heterogeneous representations.

In addition, we compute pairwise cosine similarities between all token representations in R to form a token cosine similarity matrix, where the (i, j) -th entry corresponds to the cosine similarity between tokens i and j . This matrix is symmetric by construction. We average the token cosine similarity matrix across the batch dimension to obtain a layer-wise summary of inter-token relationships. This matrix serves both as a proxy for inter-token heterogeneity and as the basis for computing the Spatial Similarity Distance Correlation (SSDC).

3.2. Spatial Similarity Distance Correlation

To quantify the emergence of spatial structure, we introduce the Spatial Similarity Distance Correlation (SSDC). For a given layer, we compute the pairwise cosine similarity matrix between token representations and the corresponding matrix of pairwise spatial distances between token positions, where Spatial distance is defined as the Manhattan distance between patch coordinates on the image grid. SSDC is defined as the Spearman rank correlation between cosine similarity and the negative spatial distance, such that higher values indicate that tokens which are spatially closer tend to have more similar representations. Because SSDC measures the monotonic alignment between spatial proximity and representational similarity, it serves as a proxy for the presence of relative positional structure in the residual stream. We use Spearman rank correlation to remain agnostic to the precise functional form relating spatial distance and representational similarity.

3.3. Fragility Score

To quantify a model’s sensitivity to distributional shifts, we define a simple *Fragility Score* (FS), which measures the relative drop in top-1 accuracy under distribution shift. It is defined as

$$\text{FS} = 1 - \frac{A_{\text{shift}}}{A_{\text{normal}}},$$

where A_{normal} and A_{shift} denote top-1 accuracy on the normal and shifted datasets, respectively. Higher values indicate greater performance degradation.

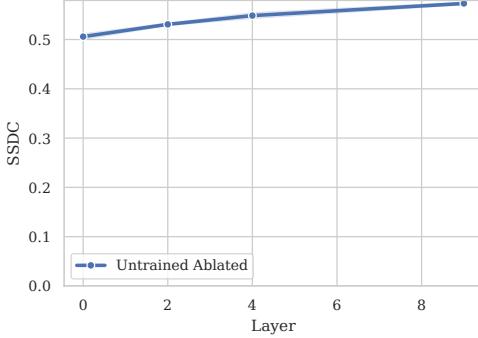

Figure 1. SSDC across depth for an untrained ablated model. SSDC remains approximately constant and at a relatively high value across layers, indicating static spatial correlations induced by architectural and data priors rather than learning. Shaded regions indicate variability across runs (± 1 standard deviation).

4. Results

4.1. Architectural Priors Induce Static Spatial Correlations at Initialization

Experimental Setup: We evaluate SSDC at layers 0, 2, 4, and 9 on the CIFAR-10 dataset using untrained ablated models. We also extract from these layers the Token Cosine Similarity Matrix and plot them. Unless stated otherwise, all reported results are averaged over 5 random seeds.

Results: The untrained ablated model exhibits a non-zero SSDC (0.5) that remains approximately constant across depth (Figure 1). This behavior is consistent across runs and indicates the presence of static spatial correlations induced by architectural and data priors rather than learning. Importantly, SSDC magnitude alone is insufficient to characterize learned spatial organization; instead, changes in SSDC across depth are the relevant signal. This static spatial structure can be visually demonstrated by token cosine similarity heatmaps that are shown in Appendix Figure 9.

This provides a static baseline against which we can measure the emergence of learned spatial structure in trained models.

4.2. Validating Emergent Spatial Structure via Extreme Counterfactuals

Experimental setup: We compute Token Cosine Similarity Matrices from layers 0, 2, 4, and 9 and evaluate the SSDC on each of these layers. We compare three settings: (i) an untrained ablated model with tokens randomly permuted at inference time, serving as an extreme baseline with no spatial structure; (ii) a trained model without positional embeddings (trained ablated); and (iii) a fully trained intact model.

Results: The untrained ablated model with random permutation consistently exhibits a near-zero and depth-invariant SSDC value, reflecting the absence of meaningful spatial

organization in token representations. This lack of structure is further evidenced by the token cosine similarity matrices (Figure 3), which display chaotic, disordered, and depth-invariant patterns at both layers 0 and 2. In contrast, the trained ablated model shows a clear and consistent increase in SSDC from layer 0 to layer 2, after which SSDC remains roughly constant across deeper layers (Figure 2). This trend is mirrored in the cosine similarity matrices, where a pronounced off-center diagonal structure emerges at layer 0 and sharpens noticeably by layer 2, indicating increasing local token similarity driven by training.

As expected, the trained intact model exhibits higher SSDC values across all layers due to explicit positional embeddings. However, the increase in SSDC and diagonal structure in the trained ablated model indicate that spatial structure can also emerge implicitly through training.

Figure 2. SSDC across depth for an untrained ablated model with random permutation, a trained ablated model, and a trained intact model.

Figure 3. Representative token cosine similarity matrices. All matrices share the same color scale.

(a) Effective Rank across depth (Intact vs Ablated vs Untrained Intact).

(b) Mean Token Cosine Similarity across depth (Intact vs Ablated vs Untrained Intact).

Figure 4. Early-layer representational diversity under intact and ablated positional embeddings. Left: Effective Rank of the residual stream across layers. Right: Mean token-wise cosine similarity across layers. Results are shown for a fully intact ViT, a model with PEs removed during training and at inference, and a completely untrained intact model. The intact model exhibits substantially higher Effective Rank at layer 0 followed by an early collapse, while the ablated model starts from a low-rank regime and remains lower on average until later layers. Mean token cosine similarity provides a complementary view, as it is higher in the ablated model than in the intact model on average across all layers.

4.3. Positional Embeddings Inject Early-Layer Representational Diversity

Experimental setup: We evaluate representational diversity in Vision Transformers using two complementary metrics: the Effective Rank of the residual stream and the mean token-wise cosine similarity. Experiments are conducted on CIFAR-10 using three model configurations: (1) a trained ViT with intact positional embeddings (PEs), (2) the same trained model with PEs removed post-hoc at inference time, and (3) an untrained model with randomly initialized, untrained PEs.

Effective Rank is computed at layers 0, 2, 4, and 9 as a proxy for the dimensional diversity of token representations. In parallel, we compute the token-to-token cosine similarity matrix at the same layers and report its mean value, which captures the degree of representational collapse across spatial tokens.

Critically, the inclusion of the untrained intact model allows us to disentangle functionally meaningful representational diversity from diversity arising due to random signal injection. Since untrained PEs are uncorrelated with image content, any diversity they induce reflects noise rather than learned structure.

Results: Figure 4 reveals a pronounced and immediate divergence in representational diversity between intact and ablated models. At layer 0, the intact model exhibits an Effective Rank approximately three times higher than that of the ablated model, indicating that positional embeddings inject substantial high-dimensional variation directly into the residual stream prior to any attention-based or data-

dependent mixing.

However, this initial diversity is not preserved. Intact models undergo a sharp collapse in Effective Rank within the first two layers, after which rank stabilizes to values comparable to those of ablated models for the remainder of the network. In contrast, ablated models begin in a low-rank regime and exhibit a more gradual evolution of rank, without the pronounced early collapse observed in intact models.

Mean token-wise cosine similarity provides a complementary view of this phenomenon. Intact models consistently display lower mean cosine similarity than ablated models in early layers (particularly layers 0 and 2), reflecting greater token-level decorrelation. As depth increases, mean cosine similarity converges across model variants, mirroring the convergence observed in Effective Rank, though intact models retain slightly lower similarity values throughout.

Importantly, these dynamics are absent in untrained intact models. Despite exhibiting elevated Effective Rank at layer 0, untrained intact models show weak variation in both metrics across depth and consistently low SSDC values that do not evolve with layer index (Figure 10). This indicates that the diversity injected by untrained PEs does not give rise to coherent spatial structure and instead behaves as unstructured noise.

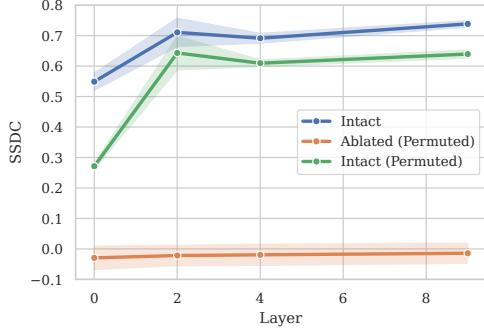

Figure 5. SSDC across depth for intact models, and intact/ablated models that have had their tokens permuted randomly at inference. The SSDC collapses to near-zero values upon permutation of the tokens of the ablated model, whereas the intact model’s SSDC only takes a slight hit after permutation.

Figure 6. Representative Token Cosine Similarity Matrices. Once its tokens are permuted, the ablated model’s Token Cosine Similarity Matrix becomes chaotic and loses all spatial structure, whereas the diagonal band persists (though fuzzier) in the intact model’s.

4.4. Patch-Relative and Absolute-Position-Based Modes of Spatial Organization

Experimental Setup: We extract Token Cosine Similarity Matrices from layers 0, 2, 4, and 9 from intact models, permuted intact models, and permuted ablated models. We plot these matrices and evaluate the SSDC across depth.

Notably, this permutation allows us to probe whether spatial organization is anchored to absolute position or emerges purely from patch content. Since token cosine similarity matrices are constructed according to token indices, this permutation disrupts the correspondence between matrix proximity and spatial proximity. Consequently, any diagonal structure observed after permutation cannot be attributed to local patch relationships and instead reflects the model’s reliance on absolute positional information.

Results: We find that ablated models collapse to near-zero SSDC values after permutation (Figure 5). Combined with the fact that these models’ performance remains unchanged under permutation due to their permutation invariance, this

indicates that ablated models form spatial structure primarily through patch content and relative relationships, without reliance on absolute token indices. As a result, permuting token order has no effect on which tokens become more similar as representations propagate through the network.

In contrast, intact models exhibit only a modest reduction in SSDC under permutation, suggesting that they rely more strongly on absolute token indices to organize spatial structure.

Interestingly, the SSDC of intact models under permutation drops sharply at layer 0 before gradually recovering across subsequent layers, remaining slightly below the unpermuted intact baseline. This pattern suggests that absolute positional information introduced by positional embeddings is progressively integrated within the encoder blocks, rather than being fully expressed at the input layer.

These trends are visually corroborated by the Token Cosine Similarity Matrices (Figure 6). In the ablated models, permutation leads to a complete collapse of spatial structure, yielding matrices that appear random and unstructured. In contrast, intact models retain a fuzzy diagonal pattern after permutation, potentially suggesting that even intact models may partially rely on patch-content for spatial structure.

4.5. Robustness Is Tightly Linked to Spatial Encoding Strategy

Experimental Setup: We evaluate Fragility Scores as defined in section 3.3 across three distinct training and inference regimes designed to disentangle patch-content-based spatial organization from absolute-position-based strategies. The first regime is an intact model, trained and evaluated under standard conditions with positional embeddings (PEs) enabled. The second is an ablated model, in which positional embeddings are removed during and after training, serving as a reference point for models that lack explicit access to absolute position information. The third regime is an intact model trained with Random Permutation Training and evaluated with Random Permutation at Inference, hereafter referred to as RPT-RPI Intact.

The RPT-RPI Intact model preserves positional embeddings throughout training and inference, but is exposed to a different random permutation of patch tokens at every forward pass. As a result, any fixed mapping between token index and spatial location is systematically destroyed. This prevents the model from exploiting absolute positional cues, even though PEs are present in the architecture. Importantly, this regime does not collapse representational diversity: prior analyses show that RPT-RPI Intact models retain a large fraction of the effective rank and avoid the degeneracies observed in fully ablated models, although diversity is not perfectly preserved. This makes RPT-RPI Intact a

Figure 7. Fragility scores for intact, ablated, and permutation-trained intact models under the stylized dataset. Black markers show the mean Fragility Scores with ± 1 standard deviation. Intact models are substantially more robust, while permutation-trained intact models exhibit fragility comparable to ablated models despite retaining positional embeddings.

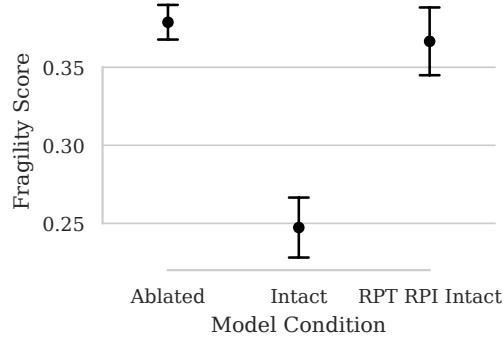

Figure 8. Fragility scores for intact, ablated, and permutation-trained intact models exposed to Gaussian Blur. Black markers show the mean Fragility Scores with ± 1 standard deviation. Intact models are substantially more robust, while permutation-trained intact models exhibit fragility comparable to ablated models despite retaining positional embeddings.

controlled intervention that selectively disables absolute-position-based strategies without inducing the broader representational pathologies associated with PE removal.

Fragility Scores are computed identically across all regimes to ensure comparability. By contrasting the intact and ablated models with the RPT–RPI Intact model, we isolate whether robustness to spatial perturbations arises from spatial organization strategy or from the Representational Diversity introduced by the PEs. In particular, if a model trained under RPT–RPI conditions exhibits high fragility despite retaining Representational Diversity, this provides direct evidence that robustness can be explained by the differences in spatial organization strategies employed by these models. A dedicated sanity check is included to verify that RPT–RPI Intact models indeed rely on patch-content-driven cues for spatial structure, rather than implicitly recovering absolute position through degenerate shortcuts in the Appendix.

RPT–RPI Intact results are averaged over 3 seeds, ablated and intact results are averaged over 5 seeds. Absolute top-1 accuracies for each of these models can be found in the Appendix (Figure 12).

Results: We consistently find that the models that rely dominantly on patch content for spatial structure (ablated and RPT–RPI Intact models) are significantly more fragile to distributional shifts than the models that rely on an Absolute Position mode of spatial organization (Figure 7 and Figure 8). In particular, the RPT–RPI Intact models exhibit Fragility Scores that are substantially higher than standard intact models and nearly comparable to fully ablated models, despite retaining representational diversity. This indicates that robustness is not merely a consequence of diverse token representations, but critically depends on the presence of absolute-position-based strategies during training and

inference.

Comparing intact and ablated models further clarifies the role of positional embeddings: intact models leverage PEs to construct stable spatial representations that mitigate sensitivity to random perturbations, while ablated models, lacking any absolute positional cues, show the lowest robustness. The RPT–RPI Intact regime provides a clean dissociation, showing that even when representational diversity is preserved, disruption of absolute positional mapping alone is sufficient to induce fragility.

Taken together, these results demonstrate that absolute-position-based spatial strategies, enabled by positional embeddings, are a key contributor to the stability of ViT representations under distributional shifts. Robustness cannot be explained solely by representational richness; the mode of spatial organization (absolute versus patch-relative) is a decisive factor. These findings complement our earlier analyses of representational geometry and spatial structure, linking internal organizational principles directly to functional resilience.

5. Discussion

Our results indicate that positional embeddings play a role that extends beyond injecting absolute positional information. Across models with intact positional embeddings, we consistently observe increased representational diversity in early layers, as reflected by elevated effective rank and reduced mean token-wise cosine similarity. This diversity persists weakly through depth and appears to act as a structural capacity rather than a direct determinant of performance. Notably, this capacity is necessary but not sufficient: RPT-RPI intact models retain high effective rank and

330 low cosine similarity while exhibiting weak performance
 331 and low robustness. The causal role of positional embeddings
 332 is further supported by post-hoc ablation experiments,
 333 where removing positional embeddings at inference time
 334 induces an immediate collapse in effective rank and increased
 335 token homogeneity, despite identical learned parameters
 336 (Appendix Section C3).

337 A natural alternative explanation for these observations is
 338 that the increased effective rank and reduced cosine simi-
 339 larity associated with positional embeddings merely reflect
 340 unstructured decorrelation or noise. Several findings argue
 341 against this interpretation. Although untrained intact mod-
 342 els also exhibit high effective rank, this diversity neither
 343 collapses across depth nor is accompanied by an increase in
 344 token-wise cosine similarity. In contrast, trained intact mod-
 345 els display a coordinated pattern in which early representa-
 346 tional diversity is progressively consolidated, with effective
 347 rank collapsing and token similarity increasing across layers.
 348 This behavior is inconsistent with stochastic noise, which
 349 would be expected to persist diffusely rather than undergo
 350 selective compression. Instead, these dynamics suggest that
 351 positional embeddings introduce a high-dimensional rep-
 352 resentational capacity that training actively organizes into
 353 structured, task-aligned subspaces.

354 Beyond representational geometry, positional embeddings
 355 also induce a qualitative shift in how spatial structure is
 356 formed. In the absence of positional embeddings, ViTs
 357 rely predominantly on patch content to infer relative spatial
 358 relationships, resulting in a content-based mode of spatial
 359 organization. When positional embeddings are present and
 360 combined with consistent patch ordering, models increas-
 361 ingly adopt an absolute-position-based strategy that lever-
 362 ages absolute positional information. While this aligns with
 363 common intuitions about the role of positional embeddings,
 364 our results indicate that this shift is not absolute: even intact
 365 models continue to subtly exploit patch content when form-
 366 ing spatial structure, suggesting that these strategies coexist
 367 rather than replace one another.

368 Finally, this shift in spatial organization has direct impli-
 369 cations for robustness. Models that rely more heavily on
 370 absolute-position-based strategies are consistently more ro-
 371 bust to distributional shifts. In contrast, content-based spa-
 372 tial organization is particularly vulnerable to perturbations
 373 that alter local patch statistics, which can disrupt the model’s
 374 ability to infer coherent spatial relationships. This supports
 375 the interpretation that positional embeddings improve ro-
 376 bustness not simply by increasing performance, but by bi-
 377 asing ViTs toward a mode of spatial reasoning that is less
 378 sensitive to changes in patch content.

379 Taken together, these findings suggest that positional em-
 380 beddings act as a structural bias that reshapes the geometry
 381 of the representation space and alters the dominant strategy

382 by which spatial information is encoded and used. Rather
 383 than serving as a passive positional signal, positional embed-
 384 dings influence how diversity is introduced, organized, and
 385 ultimately integrated into task-relevant computation, with
 386 measurable consequences for robustness and generalization.

Limitations and Future Directions

387 Despite providing a detailed mechanistic analysis, our study
 388 has several limitations. First, our experiments focus on a
 389 specific class of ViT architectures and positional embedding
 390 schemes. While we expect the qualitative distinction be-
 391 tween absolute-position-based and patch-relative strategies
 392 to generalize, the precise dynamics may vary across archi-
 393 tectures, embedding types, or training regimes. Extending
 394 this analysis to alternative positional encoding mechanisms,
 395 such as relative or rotary embeddings, remains an important
 396 direction for future work.

397 Second, our robustness evaluation centers on a particular
 398 family of distributional shifts. Although these shifts are
 399 well-motivated and commonly used, they do not exhaust
 400 the space of possible perturbations. It is possible that patch-
 401 relative strategies may confer advantages under other forms
 402 of shift not considered here.

403 Finally, our study is limited in its experimental scope: all
 404 analyses were conducted using relatively small Vision Trans-
 405 formers (approximately 12M parameters) trained on CIFAR-
 406 10. While this controlled setting enabled detailed mechanis-
 407 tic analysis, it raises natural questions about the generality
 408 of our findings. The magnitude of the effects we observe,
 409 such as the scale of the early-layer effective rank spike or
 410 the precise SSDC values may vary with model scale and
 411 dataset complexity. However, we hypothesize that the core
 412 directional conclusions are rooted in a causal, architectural
 413 mechanism. But we explicitly encourage future works to
 414 validate and quantify these effects in larger-scale, state-of-
 415 the-art ViT models.

6. Related Work

Positional Information in Vision Transformers

416 The standard Vision Transformer (ViT) breaks the permuta-
 417 tion invariance of self-attention by adding learnable absolute
 418 positional embeddings (PEs) to patch tokens (Dosovitskiy
 419 et al., 2021), establishing the dominant paradigm for spatial
 420 encoding in vision transformers. However, it has been found
 421 that ViTs retain substantial performance even when PEs are
 422 degraded or removed (Dosovitskiy et al., 2021; Chu et al.,
 423 2023), suggesting ViTs may be able to partially recover
 424 spatial structure and implicit positional information without
 425 PEs. In fact, similar observations have been reported outside
 426 the vision domain. For example, recent work on decoder-only
 427 Transformers shows that models trained without PEs

can implicitly recover positional information and that they tend to use relative positions in practice (Kazemnejad et al., 2023). While this analysis is specific to generative language models, it reinforces the broader notion that explicit PEs are not strictly required for structured positional information to emerge. This parallels earlier findings in CNNs, where it was demonstrated that convolutional networks learn substantial positional information implicitly, for instance from architectural features like zero-padding (Islam* et al., 2020). These observations create the fundamental puzzle our work addresses: if spatial structure can emerge without explicit guidance, what functional role do PEs actually play? Prior studies on PEs in ViTs have primarily focused on architectural variants (d’Ascoli et al., 2022; Liu et al., 2021) or downstream performance comparisons [2, 3], leaving the mechanistic impact of PEs on internal representations largely unexplored.

Representational Analysis of Transformers

A separate line of work analyzes the geometry and dynamics of transformer representations using tools from representational analysis. Earlier work provided foundational comparisons between ViT and CNN representations (Raghu et al., 2021), revealing distinct spatial organization patterns. Subsequent work has examined how attention mechanisms transform representations (Kobayashi et al., 2021), and the evolution of representational rank through depth (Dong et al., 2021), and the tendency for token representations to homogenize in deep layers (Bhojanapalli et al., 2021). The residual stream framework provides the conceptual foundation for our analysis of token representations across layers (Elhage et al., 2021). However, despite these insights, these representational analyses have not specifically targeted the causal effect of positional embeddings on this geometry, nor have they connected these internal dynamics to external robustness properties.

Robustness of Visual Models

Vision Transformers exhibit distinct robustness profiles compared to convolutional networks. Prior works have systematically compared ViT and CNN robustness, finding transformers exhibit greater resilience to spatial perturbations but increased sensitivity to certain texture changes (Bhojanapalli et al., 2021). Subsequent work further establishes that ViTs demonstrate favorable out-of-distribution generalization properties (Paul & Chen, 2022). These observations connect to the broader literature on shape versus texture bias in visual recognition, where it has been shown that models with stronger shape bias tend to exhibit better generalization (Geirhos et al., 2019). While robustness differences between architectural families have been documented, the link between a model’s specific spatial reasoning strategy, such as relying on absolute position versus inferring relations from content, and its robustness to distribution shifts has not been

mechanistically established.

Our Contribution

We bridge these disconnected research threads to solve the positional embedding puzzle. Unlike performance-focused ablation studies (Dosovitskiy et al., 2021; Chu et al., 2023), we perform a causal, representational analysis to show how PEs work internally. We demonstrate they (1) induce early-layer representational diversity through a high-rank injection at layer 0, (2) shift the model’s spatial organization strategy from content-relative to position-absolute reasoning, and (3) that this strategic shift—rather than representational diversity alone—confers robustness to texture-based distribution shifts. We introduce the Spatial Similarity Distance Correlation (SSDC) metric and employ controlled interventions like Random Permutation Training to isolate these mechanisms, providing the a unified and mechanistic account of why PEs remain crucial beyond their basic function of breaking permutation invariance.

7. Conclusion

In this work, we investigated how positional embeddings shape spatial organization and representation geometry in Vision Transformers. We show that even in the absence of positional embeddings, ViTs retain non-trivial spatial structure through a patch-relative, content-based mode of organization. However, this structure is fragile and corresponds to limited representational consolidation. When positional embeddings are present, they introduce substantial early-layer representational diversity and induce a qualitatively different pattern of representation dynamics, characterized by coordinated rank collapse and increased token similarity across depth.

These findings indicate that positional embeddings act as a structural bias that alters both the geometry of the latent space and the dominant strategy by which spatial information is encoded. By pushing ViTs toward an absolute-position mode of spatial organization, positional embeddings promote more stable and robust representations under distributional shift, while still allowing patch content to play a secondary role. More broadly, our results suggest that spatial reasoning in ViTs emerges from the interaction between inductive bias, training dynamics, and representational geometry, rather than from positional encoding alone. Understanding and controlling these interactions may be critical for designing transformer-based vision models that generalize reliably beyond their training distributions.

8. Impact Statements

This paper presents work whose goal is to advance the field of machine learning. There are many potential societal

440 consequences of our work, none of which we feel must be
 441 specifically highlighted here.

A. Experimental Setup and Hyperparameters

Table 1. Model architecture and training hyperparameters used in all experiments.

| Parameter | Value |
|---------------------------------|--------------------|
| <i>Input & Tokenization</i> | |
| Input resolution | 32×32 |
| Patch size | 4×4 |
| Number of patches | 64 |
| Input channels (C) | 3 |
| <i>ViT Architecture</i> | |
| Embedding dimension (D) | 320 |
| Number of encoder layers | 10 |
| Number of attention heads | 8 |
| Key/query dimension (d_k) | 40 |
| Dropout (embedding) | 0.1 |
| Dropout (attention) | 0.1 |
| Dropout (MLP) | 0.1 |
| Stochastic depth rate | 0.1 |
| <i>Training Hyperparameters</i> | |
| Batch size | 128 |
| Optimizer | Adam |
| Learning rate | 1×10^{-3} |
| Weight decay | 5×10^{-4} |
| Adam β_1 | 0.9 |
| Adam β_2 | 0.999 |
| Training epochs | 50 |

B. Metric Definitions and Implementation Details

B.1. Spatial Similarity Distance Correlation (SSDC)

Let T denote the number of patch tokens (excluding the CLS token), arranged on a $\sqrt{T} \times \sqrt{T}$ image grid. For a given layer, let $S \in \mathbb{R}^{T \times T}$ be the pairwise cosine similarity matrix between token representations. We associate each token i with spatial coordinates $\mathbf{p}_i \in \mathbb{Z}^2$ corresponding to its location on the image grid, and define the spatial distance matrix $D \in \mathbb{R}^{T \times T}$ by

$$D_{ij} = \|\mathbf{p}_i - \mathbf{p}_j\|_1,$$

where $\|\cdot\|_1$ denotes Manhattan distance.

SSDC is defined as the Spearman rank correlation between representational similarity and negative spatial distance over all unordered token pairs:

$$\text{SSDC} = \rho_{\text{Spearman}}(\{S_{ij}\}_{i < j}, \{-D_{ij}\}_{i < j}).$$

Higher SSDC values indicate that spatially proximal tokens tend to have more similar representations, reflecting stronger relative positional structure in the residual stream. We use Spearman correlation to remain agnostic to the exact functional relationship between spatial distance and representational similarity.

Effective Rank

Given a matrix $X \in \mathbb{R}^{n \times d}$ (e.g., a collection of token representations), let $\sigma_1, \dots, \sigma_r$ denote its singular values, where $r = \text{rank}(X)$. We define the effective rank of X using the participation ratio as

$$\text{erank}(X) = \frac{\left(\sum_{i=1}^r \sigma_i^2\right)^2}{\sum_{i=1}^r \sigma_i^4}.$$

550 This quantity measures how evenly variance is distributed across singular directions: it attains its maximum value of r when
 551 all singular values are equal, and decreases as the representation collapses onto fewer dominant directions.
 552

553 B.2. Mean Cosine Similarity

554 Let $R \in \mathbb{R}^{B \times T \times D}$ denote the token representations at a given layer, excluding the [CLS] token, where B is the batch
 555 size, T the number of tokens, and D the hidden dimension. For each sample in the batch, we compute the pairwise cosine
 556 similarity between all token representations to obtain a token cosine similarity matrix $S \in \mathbb{R}^{T \times T}$, where
 557

$$S_{ij} = \frac{r_i^\top r_j}{\|r_i\|_2 \|r_j\|_2}.$$

561 The similarity matrices are symmetric by construction and have unit diagonal. We average S across the batch dimension to
 562 obtain a layer-wise summary of inter-token relationships. Mean Cosine Similarity (MCS) is defined as the mean of all entries
 563 of this averaged similarity matrix. Because the diagonal entries are identically equal to 1 across all models and conditions,
 564 including them does not affect comparative analysis. Higher MCS values indicate greater representational homogeneity
 565 among tokens.
 566

567 B.3. Fragility Score

568 To quantify sensitivity to distributional shifts, we compute the Fragility Score (FS), defined as the relative drop in top-1
 569 accuracy under a given shift:
 570

$$\text{FS} = 1 - \frac{A_{\text{shift}}}{A_{\text{normal}}},$$

571 where A_{normal} and A_{shift} denote top-1 accuracy on the unshifted and shifted datasets, respectively. Higher values correspond
 572 to greater performance degradation. Unless otherwise stated, accuracies are averaged across random seeds prior to computing
 573 FS.
 574

575 B.4. Metric Summary

576 For clarity, we briefly summarize the metrics used throughout this work and the phenomena they are intended to capture.
 577

- 578 • **Mean Cosine Similarity (MCS)** measures average pairwise similarity between token representations and serves as a proxy for inter-token homogeneity or redundancy.
- 579 • **Effective Rank** quantifies representational diversity by measuring how evenly variance is distributed across singular directions of the token representation matrix.
- 580 • **Spatial Similarity Distance Correlation (SSDC)** captures the degree to which representational similarity aligns with spatial proximity, serving as a proxy for relative positional structure in the residual stream.
- 581 • **Fragility Score (FS)** measures sensitivity to distributional shifts by quantifying relative performance degradation under dataset perturbations.

582 Together, these metrics allow us to disentangle representational diversity, spatial organization strategy, and robustness, and to analyze how positional embeddings causally affect each of these factors.
 583

605 **C. Additional Analyses**
 606
 607

608 **C.1. Spatial Structure in Untrained Ablated Models**

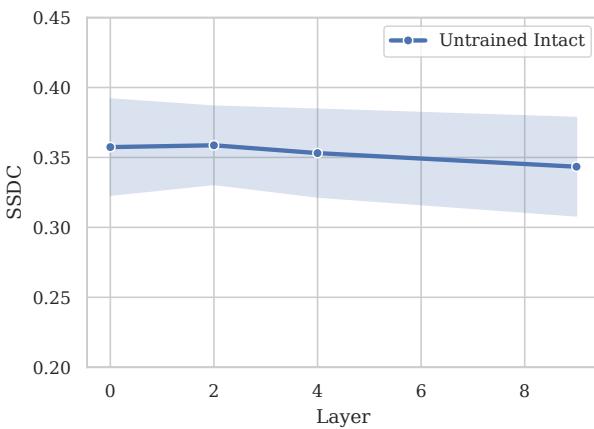

642 *Figure 9.* Batch-averaged token cosine similarity heatmaps for an untrained ablated (NoPE) model at layers 0 (top) and 2 (bottom). A
 643 diagonal spatial structure is present at initialization, but remains unchanged across layers, indicating static, architecture-induced spatial
 644 organization rather than learned positional structure.

645
 646
 647 To complement the quantitative SSDC results reported in the main text, we visualize token cosine similarity heatmaps for
 648 untrained ablated models. Figure 9 shows batch-averaged token cosine similarity matrices at layers 0 and 2, excluding the
 649 [CLS] token.

650 Despite the absence of training, a clear diagonal structure is already present at initialization, indicating that a weak form of
 651 spatial organization is implicitly induced by the model architecture and the image patchification process. However, this
 652 structure does not sharpen, diffuse, or qualitatively change across early layers, remaining essentially invariant through depth.
 653 This behavior contrasts with trained models, where spatial structure evolves with depth and reflects learned spatial reasoning
 654 strategies.

655 These visualizations support the interpretation that spatial structure observed in untrained ablated models is not emergent,
 656 but rather a static byproduct of architectural and data-induced biases.

(a) **SSDC Across Depth for an Untrained Intact Model.** SSDC remains consistently low and invariant across depth ($n = 3$ seeds), indicating an absence of coherent spatial structure despite the presence of positional embeddings.

(b) **Representative Token Cosine Similarity Matrix from an Untrained Intact Model.** The weak diagonal pattern and low overall inter-token similarity reflect disrupted spatial correlations induced by untrained positional embeddings.

Figure 10. (

Spatial Structure in Untrained Intact Models. Untrained positional embeddings suppress spatial structure by injecting unstructured positional perturbations, resulting in low SSDC and weak token-to-token correlations across depth.)

C.2. Absence of Spatial Structure in Untrained Intact Models

We observe that SSDC in the untrained intact model remains consistently low and invariant across depth. This behavior contrasts sharply with untrained ablated models and indicates an absence of coherent spatial structure. We attribute this effect to the presence of untrained positional embeddings, which introduce unstructured positional perturbations that disrupt the weak spatial correlations otherwise present in ViTs without positional encodings (Sections 4.1 and C.1).

This interpretation is supported by the representative Token Cosine Similarity Matrix in Figure 10, which exhibits a substantially weaker diagonal structure and lower overall inter-token similarity compared to the untrained ablated model (Figure 9). Together, these observations indicate that the representational diversity observed in untrained intact models does not reflect meaningful spatial organization, but rather the injection of positional noise.

In contrast, the trained intact model exhibits markedly different behavior: SSDC begins at a higher value and increases sharply from layer 0 to layer 2 (Figure 2). When considered alongside the depth-wise evolution of representational diversity, this divergence highlights a key distinction between noise-induced diversity in untrained intact models and the emergence of functionally meaningful spatial structure during early stages of training.

C.3. Effects of Post-hoc Ablation of Positional Embeddings

(a) **Mean Cosine Similarity Across Depth With and Without Positional Embeddings.** Removing positional embeddings from a trained Intact model increases similarity among token representations in early layers, reflecting a collapse of representational diversity. Intact models maintain lower early-layer similarity, highlighting the role of positional embeddings in structuring diverse representations.

(b) **Effective Rank Across Depth With and Without Positional Embeddings.** Post-hoc ablation of positional embeddings substantially reduces effective rank, particularly in early layers, confirming that positional information supports the spread and dimensionality of learned representations. Intact models maintain higher rank across layers.

(c) **SSDC Across Depth With and Without Positional Embeddings.** Removing positional embeddings lowers initial SSDC and delays the characteristic peak from layer 2 to around layer 4, which is also weaker in magnitude. This indicates that positional embeddings accelerate the formation of spatial structure in early layers and contribute to its overall magnitude.

Figure 11. **Effects of Post-hoc Positional Embedding Removal.** Removing positional embeddings from a trained Intact model causes both representational diversity and SSDC to collapse.

Upon post-hoc removal of positional embeddings from an Intact model, representational diversity collapses immediately, as expected. More interestingly, SSDC also decreases: the initial value at layer 0 is lower, and the characteristic peak observed in intact models shifts to later layers (around layer 4) and is weaker in magnitude (Figure 11). This indicates that positional embeddings not only contribute to the overall level of spatial structure but also accelerate its early-layer development. These results confirm that the learned representations in Intact models rely on positional information to establish and maintain both representational diversity and spatial organization, rather than solely on patch-content correlations.

770 771 772 773 774 775 776 777 C.4. Model Performance Across Distributional Shifts

778 We evaluate the absolute performance of our models under three conditions: the original (in-distribution) data, AdaIN
779 style transfer, and Gaussian blur. Figures 12a, 12b, and 12c summarize the results. Across all settings, the Intact model
780 consistently outperforms both the Ablated and RPT-RPI Intact models, which exhibit similar and substantially lower
781 accuracies. This pattern highlights that removing or perturbing positional embeddings diminishes functional performance,
782 while the Intact model retains robustness even under distributional shifts.
783

784
785 **Figure 12. Absolute Model Accuracies Across Distributional Shifts.** Intact models maintain substantially higher performance across all
786 shifts, whereas Ablated and RPT-RPI Intact models exhibit similar, lower accuracies. This trend underscores the functional importance of
787 intact positional embeddings.
788

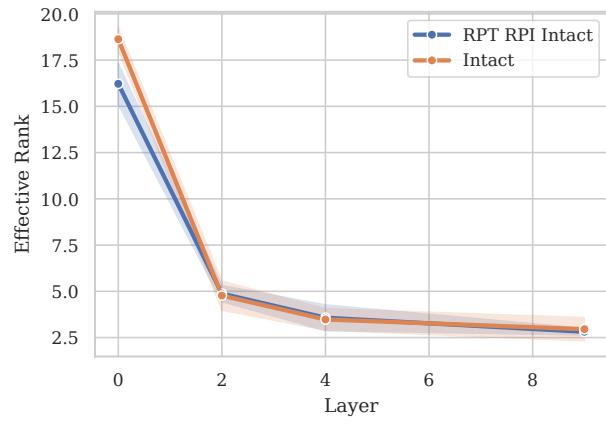

789 D. Sanity Checks

790 D.1. Patch Content Reliance in RPT RPI Intact Models

791 The results found in Figure 13 that RPT–RPI Intact models preserve substantial representational diversity while relying on
792 patch-content alignment for spatial organization. The near-zero SSDC under permutation, coupled with the recovery of
793 healthy SSDC dynamics when permutations are removed at inference (RPT–NPI Intact), demonstrates that spatial structure
794 is present but expressed through content-dependent rather than absolute positional cues. The close correspondence in
795 Effective Rank further verifies that this behavior is not driven by representational collapse. These observations serve as
796 a sanity check that RPT–RPI Intact models behave consistently with their intended design and that our metrics reliably
797 distinguish spatial structure from representational diversity.
798

(a) **Spatial Structure in RPT–RPI Intact Models.** SSDC in RPT–RPI Intact models remains near zero across depth, indicating the absence of stable spatial structure under random patch permutations. When the permutation is removed at inference (RPT–NPI Intact), SSDC exhibits non-zero values and characteristic early-layer growth between layers 0 and 2, consistent with healthy trained models. This behavior confirms that spatial structure in RPT–RPI Intact models is primarily dependent on patch-content alignment rather than absolute position. These findings are consistent across runs ($n=3$ seeds).

(b) **Representational Diversity in RPT–RPI Intact Models.** Effective Rank across layers for Intact and RPT–RPI Intact models largely overlaps, with only a slight reduction in the first layer for RPT–RPI Intact models. This indicates that representational diversity is largely preserved under random patch permutations, despite the absence of stable spatial structure.

Figure 13. Spatial Structure and Representational Diversity in RPT–RPI Intact Models. This figure compares spatial structure and representational diversity in RPT–RPI Intact models and their non-permuted inference counterpart (RPT–NPI Intact), where patch permutations are removed at inference. SSDC remains near zero under random patch permutations but recovers healthy early-layer growth when permutations are removed, indicating content-dependent spatial structure. Effective Rank closely matches that of fully Intact models across layers, with only a slight reduction in the first layer, confirming that representational diversity is largely preserved. Together, these results validate that RPT–RPI Intact models maintain diverse representations while expressing spatial structure primarily through patch-content alignment.
